Appendix A:  Well Completion Reports
Appendix B:  Sonoma County Groundwater Recharge Analysis
Introduction

The applicant is seeking permits to cultivate 6,649 square feet (0.15 acres) of cannabis at 2000 Los Alamos Road (Sonoma County APN 030-050-009), which is located in the upper Santa Rosa Creek watershed approximately 4 miles north of Kenwood near the northern edge of Hood Mountain Regional Park (Figure 1). The project parcel is located in a Class 4 groundwater area defined by Sonoma County to be an area with “low and highly variable water yield”. This hydrogeologic report was prepared as required by Sonoma County Permit and Resource Management Division (PRMD) pursuant to General Plan Policy WR-2e, Procedure and Policy 8-1-14, and section 10d of Exhibit A-2 of County Ordinance No. 6189 regarding water availability in Zone 3 and 4 areas where groundwater is believed to be of limited supply. This report only evaluates potential impacts of the proposed project to groundwater. All other plans and documents related to permitting the project are being prepared by other professionals.

This hydrogeologic report includes the following elements: estimates of existing and proposed water use within the project recharge area, compilation of well completion reports (drillers' logs) from the area and characterization of local hydrogeologic conditions, estimates of annual groundwater recharge and existing and proposed groundwater use, and the potential for well interference between the project well and neighboring wells.

Limitations

Groundwater systems of Sonoma County and the Coast Range are typically complex, and available data rarely allows for more than general assessment of groundwater conditions and delineation of aquifers. Hydrogeologic interpretations are based on the drillers' reports made available to us through the California Department of Water Resources, available geologic maps and hydrogeologic studies and professional judgment. This analysis is based on limited available data and relies significantly on interpretation of data from disparate sources of disparate quality. Existing and proposed future water use on and near the project site is estimated based on the applicant’s experience and expectations, and on regionally-appropriate water duties for the observed and expected uses.
Figure 1: Project location map.
Hydrogeologic Conditions

Overview
The project parcel is located in the mountains northeast of Santa Rosa and is underlain by Cretaceous-aged mélangé rocks of the Franciscan Complex (map unit fsr) (Figure 2). This map unit consists primarily of a sheared argillite and greywacke matrix enclosing blocks and lenses of chert, metachert, greenstone, serpentinite, and other Franciscan rocks (Graymer et al., 2007). The block underlying the project parcel is approximately 4.5 square miles and is oriented northwest to southeast, parallel to nearby faults. Surrounding rocks belong to other units of the Franciscan Complex, primarily late-Jurassic to early-Cretaceous-aged greywacke and mélangé (map unit KJfs).

The Franciscan Complex is generally considered poor aquifer material; however, successful wells of generally limited capacity are common in this highly variable geologic unit. Primary porosity in the Franciscan Complex is low and groundwater occurs primarily in fractures. Well yields are variable depending on the degree of fracturing; however, yields are generally low and on the order of a few gallons per minute; dry test holes are also common within these rocks (LCSE, 2013).

The project parcel is located near several northwest to southeast trending faults. The nearest of these is located approximately 0.25 miles northeast of the project parcel. The nearest major fault, the northwest to southeast trending St. John Mountain Fault, is located approximately 1.0 mile southwest of the project parcel.

Well Data
Well Completion Reports for wells on and around the project parcel were obtained from the California Department of Water Resources (Table 1). Well test reports were also provided by the client for two wells associated with the project parcel. A subset of these logs and reports was compiled (Appendix A) and georeferenced based on parcel and location sketch information (Figure 2).

There are two wells associated with the project parcel. The first, Well 1, is located near the existing residence at the northwestern corner of the parcel. This well was completed to a depth of 174 feet in the Franciscan mélangé (map unit fsr). At the time a pump test was performed in 1995, the well had a static water level of 107 feet and an estimated yield of 0.8 gpm (Table 1). A Geologic Log is not available for this well and the screened interval is unknown. The second, Well 2, is located west of the existing residence, south of the access road. This well was completed in 1985 to a depth of 124 feet. A surficial layer of clay, followed by alternating layers of grey sandstone and shale were encountered while drilling this well. These rock descriptions are consistent with the Franciscan mélangé (map unit fsr). At the time of completion, the static water level was 20 feet. Ten years later when a pump test was performed in 1995, the static water level was observed at 20 feet; this indicates a relatively stable groundwater resources in the vicinity of the project parcel. This well test estimated the stable yield at 1.6 gpm (Table 1).
Figure 2: Surficial geology and locations of wells in the vicinity of the project parcel. Surficial geology based on data from the Geologic Map of Parts of Eastern Sonoma and Western Napa Counties (Graymer et al., 2007)
Well Completion Reports for four additional wells were located within the vicinity of the project recharge area. All of these wells are completed in the Franciscan mélange (map unit fsr) or other similar rock types. Estimated yields ranged from 12 gpm (Well 5) to 0.75 gpm (Well 6). Static water levels were relatively consistent (15 – 21 feet).

Based on available satellite imagery, several additional wells appear to be located on the neighboring parcel to the east (APN 030-050-008). Well Completion Reports were unavailable for these wells and specific details of the wells are unknown. However, based on available topographic data, the ground surface elevation of all of these wells appear to be below the bottom of the screened intervals of both wells associated with the project parcel. In other words, the wells on the neighboring parcel are likely not screened within the same thickness of the Franciscan mélange as the project wells.

Geologic Cross-Section

A geologic cross-section oriented southwest to northeast through the project recharge area is shown in Figure 3 (see Figure 2 for location). Elevations along the cross-section ranged from approximately 1,500 feet on the ridgeline near the project parcel to approximately 900 feet in the adjacent valley bottoms. All surrounding rocks belong to various units of the Franciscan Complex. Based on water surface elevation data from wells test reports, the groundwater surface is estimated to mimic surface topography.

Project Aquifer

Within the vicinity of the project parcel, all areas are underlain by the Franciscan mélange (map unit fsr). The nearest mapped geologic contacts and faults are located approximately 0.25 miles northeast of the project parcel. Due to the compact nature and relatively low hydraulic conductivity of the Franciscan Complex, the project aquifer is not believed to extend as far as these contacts. Therefore, the project recharge area is defined based on local groundwater flow patterns which are believed to mimic surface topography.

The groundwater elevation near the ground surface in Well 2 contrasts sharply with the groundwater elevation in Well 1 (Figure 3). The near-surface water table associated with Well 2 may be associated with geologic materials in the Franciscan Complex that often manifest as deep-seated rockslides and/or earthflows. Aerial imagery of the project recharge area reveals that the ridgetop to the west of the project parcel is vegetated by grassland, and, on the opposite side of the ridge from the project parcel, gullies and hummocky terrain characteristic of earthflow terrain is evident. On the east side of the ridge where the project parcel is located, oak savannah vegetation is dominant; the upper portion of the slope is grassland contiguous with the west side of the ridge. The different characteristics of water level and well yield in Well 2 compared to Well 1 would be consistent with a perched aquifer in the “landslide” deposits (Figure 3) defined by the grassland vegetation. Well 2 is located at the eastern edge of the grassland near the top of the ridge and Well 1 is located farther to the east and downhill in the oak savannah.

The southwestern boundary of the project recharge area is defined by the prominent ridgeline near the project parcel which has been conceptualized as a groundwater divide. The northeastern boundary of the project recharge area is defined as the surface contour level with the bottom of the screened interval of the deeper well on the project parcel (Well 1, approximately 1,250 ft using the North American Vertical Datum of 1988 (NAVD 88)). The northwestern and southeastern boundaries are defined by minor ridges connecting the main ridgeline and the surface contour.

The total project recharge area is approximately 12.6 acres, all of which is underlain by the Franciscan mélange (map unit fsr). Because the project aquifer is located in fractured bedrock and clay-rich earth materials of the Franciscan Complex, it is likely that the project aquifer is confined or semi-confined.

Groundwater Storage Volume

An estimate of the total available groundwater storage within the aquifer recharge area can be obtained as the product of the project recharge area, the saturated aquifer thickness, and the aquifer specific yield. Because of the large change in elevation across the project recharge area, water surface elevation and saturated thickness are expected to have a high degree of spatially variability. Therefore, the estimated groundwater storage was calculated using a spatial average of saturated thickness across the project recharge area.
Using well test data for the two wells associated with the project parcel, the water surface appears to mimic surface topography at an average depth of 64 ft. Based on the 10m USGS DEM, the average surface elevation of the project recharge area is 1,380 ft NAVD 88 and the average water surface elevation is estimated to be 1,316 ft NAVD 88. The bottom of the deeper of the two wells associated with the project parcel is approximately 1,250 ft NAVD 88. Calculating the average saturated thickness as the difference between the average water surface elevation and the bottom of the lower screened interval of the project well yields an estimated average saturated thickness of 66 feet. This provides a minimum estimate of the saturated thickness; the Franciscan Complex extends to significantly greater depths beneath the project recharge area.

Based on the well completion report for the project well, the saturated zone is located entirely within the Franciscan Complex. While specific yield values are unavailable for the Franciscan Complex, the porosity of fractured bedrock such as the fsr unit of the Franciscan Complex is expected to lie between <1 and 10% (Freeze and Cherry, 1979; Weight and Sonderegger, 2000). To be conservative, we have used low-end estimates of specific yield of 1% for the TKfss. This results in an estimate of the available groundwater storage of 8.3 acre-ft. (66-ft x 0.01 x 12.6 acres).

**Water Demand**

Within the project recharge area, water demand was estimated for both the existing and proposed conditions. Water uses were determined using site details provided by the applicant and verified using satellite imagery. Annual use rates for the various water uses were estimated primarily based on Napa County’s Water Availability Analysis Guidance Document, dated May 2015 (Napa County, 2015). Water use rates for cannabis cultivation on the project parcel were determined based on correspondence with the applicant.

The project recharge area covers portions of four parcels: the project parcel and three adjacent parcels. Based on satellite imagery and information provided by the project applicant, none of the neighboring parcels have developed water uses within the project recharge area. While there appear to be wells and water use on the neighboring parcel to the east (APN 030-050-008), this parcel is located outside of the project recharge area and wells on this parcel are screened below the bottom of the lowest well on the project parcel (Well 1). Therefore, in both the existing and proposed conditions, the only water use within the project recharge area was assumed to be associated with the project parcel.

**Existing Condition**

The water supply system for the project parcel is comprised of Wells 1 and 2. Each well has a new pump. Well yields are 0.6 gpm and 1.6 gpm, respectively, with a combined yield of 2.4 gpm; these wells slow-pump to fill a 5,000-gallon storage tank. Half of the tank storage is allocated for fire protection; the other half is available for irrigation use.
In the existing condition, 1,563 ft² of cannabis is cultivated indoors on the project parcel. The indoor cultivation area currently houses 376 plants. The operation irrigates at a rate of 200/gal/week for each 500 ft² section, year-round. Although the use rate per plant is very low (approximately 0.24 gallons/plant/day), the size of the plants grown is also very small (less than 1 ft²/plant). Higher water use rates of several gallons per plant per day estimated for large outdoor plants (Bauer 2015) are not applicable to small plants grown indoors.

There is an agricultural barn on the project parcel; there is no residence on the parcel. The two owner-operators are the only full-time employees and were assumed to work five days per week, year round. During trimmings, independent contractors work on-site; however, the duration that these contractors are on-site, typically about three days, four times per year, requires minimal water use.

Based on these uses, existing water demand within the project recharge area is estimated at 0.12 acre-ft/yr (Table 2). The majority of this is for cannabis irrigation (Table 3) and the balance is used by employees (Table 4).

**Proposed Condition**

In the proposed condition, the indoor cultivation area will be expanded to 3,799 ft² and will house approximately 1,816 plants. Indoor irrigation rates will be comparable to the existing condition with each 500 ft² section of the indoor cultivation area using 200 gallons per week. Although the per-plant irrigation rate is less than in the existing condition, the planting density is correspondingly higher.

A 2,850 ft² mixed-light cultivation area housing 2,144 plants is also proposed. Plants will be watered bi-weekly in groups of 16. Each group of 16 plants will receive 10 gallons/watering, equivalent to 0.18 gallons/plant/day. Although the per-plant irrigation rate is low, the planting density is high. Normalized for area, plants in the mixed-light cultivation area will be irrigated at a rate of 0.13 gal/ft²/day. This is conservative compared to rates reported by other mixed-light cultivators in Sonoma county for whom OEI has previously prepared groundwater report. These cultivators typically report using 0.07 – 0.12 gal/ft²/day. The expanded operation will continue to be run by the two owner-operators with independent contractors being brought in only for short periods of time for trimming. Therefore, employee use will be minimal in the proposed condition.

</tr>
</tbody>
</table>

The total proposed water demand within the project recharge area is estimated to increase by 0.57 acre-ft/yr to 0.69 acre-ft/yr (Table 2). All of this proposed increase comes from increases in irrigation use (Table 5). All water use comes from the project parcel which comprises approximately 64% of the project recharge area.

**Groundwater Recharge Analysis**

Groundwater recharge within the project recharge area was estimated using a Soil Water Balance (SWB) model developed for Sonoma County and portions of Marin County. The SWB model was developed by the U.S. Geological Survey (Westenbroek at al., 2010) and produces a spatially distributed estimate of annual recharge. This model operates on a daily timestep and calculates runoff based on the Natural Resources Conservation Service (NRCS) curve number approach and Actual Evapotranspiration (AET) and recharge based on a modified Thornthwaite-Mather soil-water-balance approach (Westenbroek et al., 2010). Details of this model are included in Appendix C.
Groundwater recharge was simulated for Water Year 2010 which was selected as precipitation was close to the 30-year average for much of Sonoma County. In Water Year 2010, recharge varied across the project recharge area from 6.2 to 11.7 inches with a spatially averaged recharge of 9.5 inches. Groundwater recharge estimates can also be expressed as a total volume by multiplying the calculated recharge by the project aquifer recharge area of 12.6 acres. This calculation yields an estimated mean annual recharge of 10.0 acre-ft/yr.

**Comparison of Water Demand and Groundwater Recharge**

The total proposed groundwater use for the project recharge area is estimated to be 0.69 acre-ft/yr, all of which is from the project parcel. Groundwater use in the project recharge area is equivalent to 6.9% of the estimated mean annual groundwater recharge of 10.0 acre-ft/yr, indicating that there is a substantial surplus of groundwater resources (Table 6). Given the magnitude of the surpluses, the small amount of groundwater use proposed by the project is unlikely to result in significant reductions in groundwater levels or depletion of groundwater resources over time.

**Potential Impacts to Streams and Neighboring Wells**

Based on available well completion reports, the nearest well (Well 3) is located 1,600 feet northeast of the nearest of the two wells associated with the project parcel (Well 1). Potential wells on the neighboring parcel to the east may be closer. The nearest potential well location on this parcel is approximately 500 feet southeast of Well 1. However, both Well 3 and the potential wells on the neighboring parcel are located outside of the project recharge area. As such, it is unlikely that increased pumping in Well 1 will result in negative impacts at either of these two wells. Similarly, there are no streams within the project recharge area.

**Summary**

Application of the Soil Water Balance (SWB) model to the project recharge area revealed that average water year recharge was approximately 9.5 inches/yr or 10.0 acre-ft/yr. The total proposed Water Use for the project aquifer recharge area is estimated to be 0.69 acre-ft/yr. This represents 6.9% of the estimated mean annual recharge indicating that the project is unlikely to result in declines in groundwater elevations or depletion of the groundwater resources over time.

FORM 25
APPENDIX B

SONOMA COUNTY GROUNDWATER RECHARGE ANALYSIS
Sonoma County Groundwater Recharge Analysis

Introduction
Developing accurate estimates of the spatial and temporal distribution of groundwater recharge is a key component of sustainable groundwater management. Efforts to quantify recharge are inherently difficult owing to the wide variability of controlling hydrologic processes, the wide range of available tools/methods for estimating recharge, and the difficulty in assessing the accuracy of estimates because direct measurement of recharge rates is, for the most part, infeasible.

Numerical modeling is a common approach for developing recharge estimates. Soil-water-balance modeling is one category of numerical models particularly well-suited for estimating recharge across large areas with modest data requirements. This study describes an application of the U.S. Geological Survey’s (USGS) Soil Water Balance Model (SWB) (Westenbroek et al., 2010) to develop spatial and temporal distributions of groundwater recharge across Sonoma County. Hydrologically connected portions of Marin County, including the San Antonio Creek and Walker Creek watersheds, were also included in the model domain. This model operates on a daily timestep and calculates surface runoff based on the Natural Resources Conservation Service (NRCS) curve number method, actual evapotranspiration (AET), and recharge based on a modified Thornthwaite-Mather soil-water-balance approach (Westenbroek et al., 2010).

It is important to note that the SWB model focuses on surface and soil-zone processes and does not simulate the groundwater system or track groundwater storage over time. The model also does not simulate surface water/groundwater interaction or baseflow; thus, the runoff estimates represent only the surface runoff component of streamflow resulting from rainstorms and the recharge estimates represent only the infiltration recharge component (also referred to as diffuse recharge) of total recharge (stream-channel recharge is not simulated).

Model Development
The model was developed using a 1 arc-second (90.8-ft) resolution rectangular grid. Water budget calculations were made on a daily time step. Key spatial inputs included a flow direction map developed from the USGS 1 arc-second resolution Digital Elevation Model (DEM), a land cover dataset derived from the Sonoma County Veg Map Lifeform dataset supplemented by the U.S. Forest Service (USFS) CALVEG dataset for portions of Marin County (Figure 1), a distribution of Hydrologic Soil Groups (A through D classification from lowest to highest runoff potential; Figure 2), and a distribution of Available Water Capacity (AWC) developed from the NRCS Soil Survey Geographic Database (SSURGO) (Figure 3).

A series of model parameters were assigned for each land cover type/soil group combination including a curve number, dormant and growing season interception storage values, and a rooting depth (Table 1). Curve numbers were assigned based on standard NRCS methods. Interception storage values and rooting depths were assigned based on literature values and

Figure 4: Soil-moisture-retention table (Thornthwaite and Mather, 1957).
previous modeling experience. Infiltration rates for hydrologic soil groups A through D were applied based on Cronshey et al. (1986) (Table 2) along with default soil-moisture-retention relationships based on Thornthwaite and Mather (1957) (Figure 4).

The SWB model utilizes daily precipitation and mean daily temperature data derived from climate stations. To account for the spatial variability of these parameters, daily precipitation and mean daily temperature were input as gridded time-series. The gridded precipitation time-series was created using data from 22 weather stations in Sonoma County, and the gridded mean temperature time-series was created using data from 10 stations (Table 3, Figures 5 & 6). These stations were selected based on completeness of the records and to provide station data across the range of climates experienced in the county. Temperature and precipitation data were obtained from the California Data Exchange Center (CDEC), the Western Regional Climate Center (WRCC), the National Climatic Data Center (NCDC), and data collected by O’Connor Environmental, Inc. from work on prior projects.

To create the gridded time-series, the model domain was divided into discrete areas represented by individual weather stations (Figures 7 and 8). This delineation was based on the USGS HUC-10 watersheds, local knowledge of climate variations across the county, and climate variations described by existing gridded mean annual (1981-2010) precipitation and temperature data (PRISM, 2010).

For the precipitation time-series, each area representing a weather station was subdivided into three to fifteen zones based on PRISM-derived 2-inch interval mean annual precipitation zones. The ratio of mean annual precipitation within a given zone and at a given gauge location was used to define scaling factors for each zone. The raw station data (daily precipitation) was then multiplied by the scaling factor to develop the final timeseries for each zone. The resulting gridded time-series is comprised of 215 individual time-series based on the scaled station data from the twenty-two stations.

The assignment of temperature stations was based on the understanding that the 10 available stations represent distinct climate zones in Sonoma County. Coastal climate conditions are best represented by the Fort Ross and Bodega Bay weather stations. The Occidental station is most representative of climate conditions in the coastal mountains of western Sonoma County, and the St. Helena station is most representative of conditions in the mountains of eastern Sonoma County. The remaining 6 stations all represent climate conditions in the inland valley bottom areas of the county. The temperature areas were not divided into additional zones for scaling because variations in temperatures within each representative area are expected to be relatively minor compared with the variations in precipitation; also the model sensitivity to temperature is expected to be small compared to the sensitivity to precipitation.

Missing and suspect data was encountered in the raw precipitation and temperature data from the weather stations used by the model. Values that were significantly outside the typical range and where similar outlying observations were not observed at nearby stations were removed from the datasets. These and missing values were filled using scaled data from other nearby
stations. Precipitation data was scaled using the ratio of the 1981 to 2010 mean annual precipitation (PRISM 2010) between the two stations. Temperature data was scaled using the ratio of the 1981 to 2010 mean monthly minimum and maximum temperatures (PRISM, 2010) between the two stations.

The current analysis focuses on a Water Year 2010 (October 1, 2009 – September 30, 2010). This year was selected because it represents a recent year with data available from most weather stations in the county, and the total annual rainfall was near long-term average conditions at most of the weather stations. Water year 2010 rainfall ranged from 83% of long-term average conditions at the Sonoma and Petaluma 10.1 W station to 137% at the Fort Ross station based on a comparison between the station data and the 1981-2010 average precipitation from PRISM (2010) (Table 3).

Model Calibration
To provide a means of calibrating the Sonoma County SWB model, streamflow data was compiled from five gauges with available data for water year 2010 (Figure 9, Table 4). These gauges were selected because they represent relatively small watersheds without significant urbanization, diversions, groundwater abstraction, reservoir impoundments, or large alluvial bodies where significant exchanges between surface water and groundwater may be expected. These attributes are desirable because the hydrographs can more readily be separated into surface runoff and baseflow components and the surface runoff pattern is more directly comparable to the SWB simulated surface runoff which does not account for water use, reservoir operations, or surface water/groundwater exchange. An overview of hydrograph separation methods may be found in Healy (2010, pp. 85-90).

We utilized the web-based Hydrograph Analysis Tool (Lim et al., 2005) to perform baseflow separations on the gauge records using the recursive digital filter method (Eckahardt, 2005) and default filter parameters for perennial streams with hard rock aquifers. Total monthly surface runoff volumes were compiled for each gauge and compared to the mean monthly surface runoff volumes predicted by SWB within each corresponding watershed area. SWB utilizes a simplified routing scheme whereby surface runoff is routed to downslope cells or out of the model domain on the same day in which it originates as rainfall, thus it is not capable of accurately estimating streamflow over short-time frames. The use of the total monthly surface runoff volumes provides a means of calibrating the model to measured surface runoff data within the limitations of the model’s routing scheme.

The model successfully reproduced the seasonal variations in surface runoff at all five gauge locations (Figure 10). Monthly Mean Errors (ME) ranged from -0.2 to 0.4 inches with a mean value of 0.1 inches (Table 5). Monthly Root Mean Square Errors (RMSE) ranged from 0.5 to 1.5 inches with a mean value of 1.0 inches. Annual surface runoff totals ranged from an under-prediction of approximately 10% at Franchini Creek to an over-prediction of approximately 19% at Buckeye Creek, with a mean over-prediction of approximately 6% across the five stations (Table 5). These results indicate that the SWB model was able to reproduce monthly surface runoff volumes with a reasonable degree of accuracy and that the model tends to over-predict surface runoff somewhat, suggesting that the model may generate a low-range estimate of recharge.

Model Results
The principal elements of the annual water budget simulated with the Sonoma County SWB model for water year 2010 are shown in map form in Figures 12 through 16 and in tabular form (sorted by total annual precipitation) for 23 major watershed areas in the county in Table 6. The watersheds areas are a modified version of the USGS HUC-10 watersheds and are named for the stream which comprises the largest proportion of the area; although in many cases the areas consist of multiple tributary streams (Figure 11).

Water year 2010 precipitation varied from 26.1 inches in the Lower Sonoma Creek watershed to 70.7 inches in the Austin Creek watershed (Table 6, Figure 12). Actual evapotranspiration (AET) ranged from 17.9 inches in the San Antonio Creek watershed to 29.5 inches in the Pena Creek watershed (Table 6, Figure 13). Surface runoff ranged from 4.0 inches in the Lower Sonoma Creek watershed to 28.1 inches in the Austin Creek watershed (Table 6, Figure 14). Recharge ranged from 5.0 inches in the Lower Sonoma Creek watershed to 16.4 inches in the Austin Creek watershed (Table 6, Figure 15). Small decreases in soil moisture storage (up to 0.8 inches) occurred in 16 of the 23 watersheds and small increases (up to 0.8 inches) occurred in the remaining watersheds (Table 6, Figure 16).

When expressed as a percentage of the annual precipitation, AET ranged from 37% in the Austin Creek watershed to 69% in the Lower Sonoma Creek watershed (Table 7). Surface runoff ranged from 15% of precipitation in the Lower Sonoma Creek watershed to 40% in the Austin Creek watershed. The variations in recharge as a percentage of precipitation is relatively narrow ranging from 19% in the Lower Sonoma Creek watershed to 27% in the Salmon Creek watershed (Table 7).

Discussion and Conclusion
Previous modeling studies have estimated water budget components in several larger watershed areas in the county including the Santa Rosa Plain, the Green Valley and Dutch Bill Creek watersheds, and the Sonoma Valley (Farrar et. al., 2006; Kobor and O’Connor, 2016; Woolfenden and Hevesi, 2014). Comparisons to these water budgets are useful for evaluating the SWB results. One would not expect precise agreement owing to significant variations in climate, land cover, soil types, underlying hydrogeologic conditions, and different spatial scales of modeling studies. These regional analyses estimated that AET was equivalent to between 44% and 49% of mean annual precipitation which is consistent with this analysis where the county-wide AET was equivalent to 48% of the annual precipitation. The regional analyses estimated that surface runoff ranged from 37 to 55% of the annual precipitation which is somewhat higher than this analysis where the equivalent county-wide value was 29%. In the regional analyses, recharge varied from 7% to 19% of the annual precipitation. The equivalent county-wide value from this study is somewhat higher at 22%.

At the local scale, the simulation results indicate sensitivity of the water budget components to variations in topographic position, land cover, and soil texture, however at the watershed scale much of the variation in the principal water budget components (AET, surface runoff, and recharge) are correlated with variations in precipitation across the county (Figure 17). AET increases as a function of precipitation in watersheds with annual precipitation up to about 45 in/yr. Above 45 in/yr AET remains relatively constant (average of about 27 in/yr). This suggests that in portions of the county experiencing low precipitation, AET is limited by available soil moisture in contrast to areas of the county with higher precipitation where AET is limited by the potential ET. Although surface runoff varies more or less linearly as function of precipitation (Figure 17), the slope of the relationship with precipitation increases above precipitation of about 45 in/yr. This suggests that surface runoff increases with precipitation more sharply where precipitation is great enough to fully satisfy potential ET. Recharge also varies linearly as a function of precipitation (Figure 17).

The recharge estimates presented here arguably represent the best available county-wide estimates produced at a fine spatial resolution using a consistent and objective data-driven approach. The current analysis focused on a single water year, 2010, and was calibrated to streamflow gauge-derived monthly surface runoff rates at five locations. Future work to expand the analysis to additional water years and calibrate to additional gauge locations would help to further evaluate, refine, and quantify the uncertainty associated with the model’s recharge estimates.
Figure 17: Principal water budget components simulated with the SWB model for major watersheds in Sonoma County as a function of annual precipitation. Trend lines fit by eye.
